

A Coupled Markov Chain Approach to Risk Analysis of Credit Default Swap Index Products*

Ronald Hochreiter[†] David Wozabal[‡]

November 19, 2009

Abstract

We apply a Coupled Markov Chain approach to model rating transitions and thereby default probabilities of companies. We estimate parameters by applying a maximum likelihood estimation using a large set of historical ratings. Given the parameters the model can be used to simulate scenarios for joint rating changes of a set of companies, enabling the use of contemporary risk management techniques. We obtain scenarios for the payment streams generated by CDX contracts and portfolios of such contracts. This allows for assessing the risk of the current position held and design portfolios which are optimal relative to the risk preferences of the investor.

1 Introduction

The analysis and valuation of structured credit products like Collateralized Debt Obligations (CDO) and Credit Default Swap Indices (CDX) gained significant importance during the sub-prime mortgage crisis since 2007. Financial institutions still hold many products for which the risk exposure is unknown.

The core problem of the recent sub-prime mortgage crisis and the connected turmoil on financial markets is that the risk of portfolios of certain asset backed securities were grossly underestimated. In particular the implicit underestimation of dependencies of default events and the resulting overestimation of the credit quality of products resulting from (repeated) tranching proved to be highly problematic.

It turned out that common risk factors related to the U.S. economy in general and to the housing market in particular lead to huge losses for a certain type of financial products (mainly mortgage backed CDOs), that were previously rated super senior.

To avoid such situations in the future it is crucial to model correlations between default events and the common risk factors carefully and fully understand the effects of these dependencies on complicated structured products.

There exist many models for describing the joint default behavior of companies in the literature (for an excellent survey and classification see for example [5, 6, 7, 8, 9] or [14]). In this paper we use a so called coupled Markov chain model (originally published in [11]) to capture dependency between credit events. Rating transitions of companies are modeled as discrete Markov chains and dependence between rating (and therefore also default) events is achieved by coupling the involved Markov chains.

Although rating based models have been criticized (see [1, 4, 13, 17]) for their sluggish response to fast evolving events (like a rapid credit quality deterioration of a company), they have the advantage that they are based on a (usually) reasonable assessment of the credit worthiness of the debtor (combining a range of qualitative and quantitative approaches) and are therefore a signal for the credit quality of the debtor, which is consistent over time as well as among different debtors. On the other hand structural models like the KMV model (see for example [4]) that strongly depend on the asset value of the company under consideration suffer from the problem of overreaction to changes in the market - especially in time of crises or boom. This leads to gross over- or underestimation of credit risk associated with a loan portfolio. Rating based approaches offer a more stable assessment, since big rating agencies aim for ratings that reflect default probabilities *through the cycle*.

Furthermore rating based evaluations are of increasing importance since pending new banking regulation uses ratings as an important input for calculating capital requirements for banks (see [3]).

The most commonly used rating based approach to modeling credit risk is used in the popular CreditMetrics software. The main idea behind CreditMetrics is similar to the ideas in this paper: the current rating of a company influences the default probability in the next period. However, the crucial difference is that in the CreditMetrics model the ratings are treated merely as *signals* which are used to calibrate a multi-variate normal copula model for the joint rating transitions (see [14] for a discussion). Hence, the model assumes a parametric distributional model for the joint behavior of the rating changes. While this assumption might be reasonable in a normal economic environment, it often fails to model the default behavior appropriately in times of crisis (where the corresponding distributions are typically non-normal due to lack of symmetry and heavy-tailedness), i.e. in situations when a correct assessment of downside risk is needed most.

The coupled Markov model discussed in this paper avoids these assumptions and models the joint behavior of the debtors in a non-parametric setting, constrained only by the assumed functional form of the rating transitions. The model is similar to the models presented in [15, 16, 21] in the sense that it is a rating based model that can be represented as a mixture model.

In [15, 16] the authors propose a generalized linear mixed model (GLMM) for rating transitions which is estimated using Bayesian techniques (GIBBS sampler). The model systematic risk factors as a combination of fixed and random effects and also allows for serial correlations in the unobserved risk factors and hence for so called *rating momentum* on a macroeconomic scale.

In [21] a model for a continuous *credit worthiness* variable is proposed which are translated to discrete ratings by identifying a rating class with an interval of the credit worthiness score. The continuous credit worthiness variable is allowed to depend on obligor specific as well as macroeconomic factors, the latter are used to model dependencies in rating transitions of different obligors.

The contribution of the paper is twofold:

1. We develop methods of statistically estimating the parameters of the credit migration model published in [11] and thereby enabling the use of the model for risk measurement and management purposes via Monte Carlo sampling from the fitted model.
2. Returns from credit portfolios typically have highly skewed distributions - a characteristic further amplified by repeated tranching as observed in the markets in the recent years. One aim of this paper is to demonstrate that because of this fact risk management techniques are essential, when deciding on portfolios of structured credit products - not only ex-post to determine how much risk capital is needed to secure existing positions but also ex-ante to design optimal portfolios relative to the risk preferences of the investor.

In the second part of the paper we use Monte Carlo simulation techniques to obtain scenarios for the payouts of financial products like CDX contracts. These scenarios

are subsequently used to capture portfolio effects inherent in the considered structured loan products and their impact on the risk characteristics of portfolios containing such products. Using the distributional information obtained by the credit migration scenarios, we outline an optimization framework which can be used for active risk management for portfolios of CDX tranches and demonstrate the power of the approach by numerical examples.

This paper is structured as follows: Section 2 is devoted to a short review of the coupled Markov chain approach. In Section 3 we discuss a maximum likelihood approach which is subsequently used to estimate the parameters of the model from empirical data. In Section 4 financial products based on Credit Default Indices are described while section 5 uses the coupled Markov chain model to calculate fair spreads for standard tranches of the iTraxx index. Finally in Section 6 portfolio optimization techniques are applied to portfolios of structured credit products - explicitly modeling the (joint) risk in the portfolios, while Section 7 concludes the paper.

2 The Model

This section gives an overview of the coupled Markov chain model introduced by [11] and is included to keep the paper self contained. The interested reader is referred to the original work for further details on the model.

Consider a diversified portfolio consisting of debt obligations of different firms. The debtors are non-homogeneous in their credit ratings and they belong to different industry sectors. Assume that there are M non-default rating classes. The ratings are numbered in a descending order so that 1 corresponds to the safest class, while M is next to the default class. For example, in terms of the rating scheme of Standard and Poor's (S&P), $1 \longleftrightarrow AAA$, $2 \longleftrightarrow AA$, $3 \longleftrightarrow A$, $4 \longleftrightarrow BBB$, $5 \longleftrightarrow BB$, $6 \longleftrightarrow B$, $7 \longleftrightarrow CCC$, $8 \longleftrightarrow CC$, $9 \longleftrightarrow C$ and $10 \longleftrightarrow D$ with $M = 9$.

The methodology suggested in [11] describes joint rating transitions of companies with different rating classes belonging to different industry sectors, such that

1. migrations of companies having the same credit rating are dependent;
2. evolution of companies through credit ratings are dependent;
3. every individual migration is governed by a Markovian matrix, which is the same for all the companies.

The model assumes that the rating process of each debtor is Markov with identical rating transition matrix and that these processes are coupled in such a way that they are statistically dependent through their common dependence on systematic factors. The specification of this dependency structure can be seen as the main contribution of the model.

Note that there is some empirical evidence hinting to the fact that the Markov assumption of credit ratings does not always hold (see [1, 13, 17]). Nevertheless this assumption is implicit in most of the popular credit risk models (also in the structural models) since it greatly simplifies the analysis. As the assumption does not seem to be *too wrong* (as shown in [12]), we do not consider more complicated models.

Let $p_{i,j}$ be the probability of transition within one year from the i -th credit rating to the j -th. In particular, $p_{i,M+1}$ is the probability that a debtor who is currently rated with i -th credit rating defaults by the end of the year. The $M \times (M+1)$ transition matrix $P = (p_{i,j})$ can be estimated using one of the various techniques proposed in literature for this purpose and is also reported by the rating companies themselves. Since we are mainly concerned with the coupling of the rating processes we assume the matrix P to be given.

Consider $X(t)$, $t \geq 1$, a discrete-time Markov chain evolving in the state space $\{1, 2, \dots, M+1\}$ governed by the probabilities $p_{i,j}$, whose absorbing state is $M+1$. Suppose the evolution of the total portfolio is modeled by a multi-dimensional random process $X^t = (X_1^t, \dots, X_N^t)$

whose components evolve like $X(t)$, but are dependent. Denote by $s(n)$ the industry sector of firm n .

Since X_n^t is modeled as time-homogeneous Markov process, it would suffice to look at the transition from time $t = 1$ to time $t = 2$ and we could therefore drop the index t for the description of the probabilistic model. However, because we need the time index t in the portfolio selection models in Section 5 and 6, we will keep the subscript to have consistent notations throughout the paper.

The starting point of the analysis for the proposed model is the commonly used division of risk factors in an idiosyncratic and a systematic factor.¹

To model dependencies between the rating transitions the discussed model also follows this intuition and splits the rating movement of company n at time t in two components: an idiosyncratic component η_n^t and a systematic component ξ_n^t . The distribution of both components depends on the current rating class of the company and the non-trivial joint distribution of the η_n^t is used to model dependency between the rating processes of the companies in the portfolio.

The mixing between the two components is achieved via a Bernoulli variable δ_n^t depending on the rating class of company n at time $t - 1$, i.e. X_n^{t-1} as well as the industry sector $s(n)$ of company n . We write

$$\mathbb{P}(\delta_n^t = 1 \mid X_n^{t-1} = m, s(n) = s) = q_{m,s}$$

and organize the respective probabilities in the matrix

$$Q = (q_{m,s})_{1 \leq m \leq (M+1), 1 \leq s \leq S}.$$

Note that the sectoral classification used in this paper as an input for the model can be replaced by any arbitrary (discrete) classification scheme for companies without structurally changing the model. Possible alternative classifications could for example be size or geographic origin of the company.

The rating of company n at time t is given by²

$$X_n^t = \delta_n^t \xi_n^t + (1 - \delta_n^t) \eta_n^t.$$

The variables δ_n^t and ξ_n^t are independent of everything else, while the variables η_n^t are independent of the δ_n^t and the ξ_n^t but have a non-trivial dependency structure within a given time period. The marginal distribution of the ξ_n^t and the η_n^t is dependent on the current rating class of the company n and the respective distribution resulting from the transition matrix P , i.e.

$$\mathbb{P}(\xi_n^t = i) = p_{X_n^{t-1}, i}, \quad \forall i \in \{1, \dots, M+1\}$$

and

$$\mathbb{P}(\eta_n^t = i) = p_{X_n^{t-1}, i}, \quad \forall i \in \{1, \dots, M+1\}. \quad (1)$$

To describe the dependency structure of the η_n^t we need several steps. First note that any transition of a discrete Markov chain η_n^t may be divided in two moves. One of them determines only the *tendency* of the move (i.e. up or down), while the other one determines

¹Similar to the classical one factor Gaussian model where the asset value used to determine the probability of default is modeled in dependence of an idiosyncratic factor and a systematic factor which is common to all the companies

²Note that in [11] the ratings were described by the slightly different model

$$X_n^t = \delta_n^t \xi_n^t + (1 - \delta_n^t) \eta_{X_n^{t-1}}^t$$

where there are only $(M+1)$ variables η . Which variable is relevant for firm n was determined by the rating class of n in the previous time period. In this way dependency was introduced between the companies in the same rating class. Although the approach followed here uses a separate variable η_n^t for every company, dependency between these variables is modeled in an analogous way (see discussion below).

the *magnitude* of the change. To be more specific let χ_m^t for $m = 1, \dots, M$ be Bernoulli tendency variables for the Markov process η_n^t . These variables determine whether a non-deteriorating move takes place for company n with $X_n^{t-1} = m$, i.e.

$$\chi_m^t = \begin{cases} 1, & \eta_n^t \geq \eta_n^{t+1} \\ 0, & \eta_n^t < \eta_n^{t+1}. \end{cases}$$

In other words, χ_m^t is the indicator of a non-deteriorating move at time t . If the probability of transitions are given by the matrix P as in (1) the tendency variable has a Bernoulli distribution whose probability of a success reads

$$p_i^+ := \sum_{j=1}^i p_{i,j} = \mathbb{P}(\chi_n^t = 1 \mid X_n^{t-1} = i).$$

Observe that there are not N but only M tendency variables per time period t , meaning that each of these determines the tendency of all the variables η_n^t for the subset of companies belonging to a specific rating class. This renders the variables η_n^t dependent via their common components $\chi^t = (\chi_1^t, \dots, \chi_M^t)$ and the non-trivial joint distribution of the same.

Conditioned on the tendency, the second move determines the magnitude of the change and follows the distribution

$$\mathbb{P}(\eta_n^t = j \mid X_n^{t-1} = i, \chi_{X_n^{t-1}}^t = 1) = \begin{cases} p_{i,j}/p_i^+, & j \leq i, \\ 0, & j > i \end{cases}$$

and

$$\mathbb{P}(\eta_n^t = j \mid X_n^{t-1} = i, \chi_{X_n^{t-1}}^t = 0) = \begin{cases} p_{i,j}/(1 - p_i^+), & j > i \\ 0, & j \leq i. \end{cases}$$

The above deconstruction of a rating move in a *tendency* and a *magnitude* is useful, since the tendency part can be used to model the dependencies between different debtors via the joint distribution of $\chi^t = (\chi_1^t, \dots, \chi_M^t)$. Given the tendencies the distribution of the magnitude is completely determined by the marginal distribution of the rating transitions, i.e. the matrix P . Note that the variables $\eta_n^t \mid \chi_{X_n^{t-1}}^t$ are independent of one another.

As mentioned above the presented model can be viewed as a Bernoulli mixing model, i.e. a model where the default probability of company n is dependent on some common factors χ and

$$\mathbb{P}(X_n^t = (M+1) \mid \chi) = p_n(\chi)$$

with the influence function $p_n : \text{range}(\chi) \rightarrow [0, 1]$. In the above case we have

$$p_n(\chi) = p_{X_n^{t-1}, M+1} q_{X_n^{t-1}, s(n)} + \mathbb{1}_{\{0\}}(\chi_{X_n^{t-1}})(1 - q_{X_n^{t-1}, s(n)}) \frac{p_{X_n^{t-1}, M+1}}{p_{X_n^{t-1}}^-}.$$

Unlike in other Bernoulli mixture models the common factors χ are not explicitly modeled as economic factors but are mere statistical phenomena.

In the original paper pairwise correlations between the tendency variables were assumed to be known and the joint distribution of these variables was found by an optimization approach (see [11] for further details). The probabilities in Q were manually tuned for small models, to demonstrate the models flexibility and expressiveness. However to use the model in practice numerically tractable estimation routines are needed to obtain realistic parameter estimates for Q and P_χ .

For a model instance with M non-default rating classes and S industry sectors and known transition matrix P , there are $S \times M$ unknown parameters in Q and $2^M - (M+1)$ for the specification of the joint distribution $\chi^t = (\chi_1^t, \dots, \chi_M^t)$. In the next section we will describe how to estimate these parameters given data on joint rating transitions via a maximum likelihood approach.

3 Estimation of Parameters

We consider the model

$$X_n^t = \delta_n^t \xi_n^t + (1 - \delta_n^t) \eta_n^t, \quad (2)$$

described in Section 2 where

$$\mathbb{P}(\xi_n^t = i) = \mathbb{P}(\eta_{X_n^{t-1}, i}^t) = p_{X_n^{t-1}, i}$$

is assumed to be known. Given a set of realizations of the rating process for N firms $X = (x^1, \dots, x^T) \in \mathbb{R}^{(N, T)}$ of the N dimensional process X^t for different rating and industry classes over a period of T time steps, we want to estimate the parameters $Q = (q_{i,j})_{i,j}$ and the joint probability mass function P_χ for $\chi = (\chi_1, \dots, \chi_M)$ by a maximum likelihood approach. Since we model rating transitions via a coupled Markov chain approach, X provides us with $N(T-1)$ realizations of the process (2) (for different industry classes and rating classes), but only with $(T-1)$ (hidden) joint realizations of $\chi = (\chi_1, \dots, \chi_M)$. It follows that we can analyze every time step separately, but have to take into consideration the joint behavior of moves within each step. In the following we derive the likelihood function by conditioning.

The likelihood of the matrix X given the matrices Q and P_χ , is

$$L(X; Q, P_\chi) = \prod_{t=2}^T \mathbb{P}(X^t = x^t \mid X^{t-1} = x^{t-1}) \quad (3)$$

and by the law of total probability

$$\mathbb{P}(X^t = x^t \mid X^{t-1} = x^{t-1}) = \sum_{\bar{\chi} \in \{0,1\}^M} P_\chi(\chi^t = \bar{\chi}) \mathbb{P}(X^t = x^t \mid \chi^t = \bar{\chi}, X^{t-1} = x^{t-1})$$

where $X^t = (X_1^t, \dots, X_N^t)$ and $\chi^t = (\chi_1^t, \dots, \chi_M^t)$. We further have because of independence of χ^t and η^t

$$\begin{aligned} \mathbb{P}(X^t = x^t \mid \chi^t = \bar{\chi}, X^{t-1} = x^{t-1}) = \\ \sum_{\bar{\delta} \in \{0,1\}^N} \mathbb{P}(X^t = x^t \mid \chi^t = \bar{\chi}, \delta^t = \bar{\delta}, X^{t-1} = x^{t-1}) \mathbb{P}(\delta^t = \bar{\delta}) \end{aligned}$$

with $\delta^t = (\delta_1^t, \dots, \delta_N^t)$.

To calculate the above sum it is necessary to divide the companies into groups and consider all possible realizations in the considered subgroups separately. Define $I^t(s, m_1, m_2)$ to be the number of companies in sector s which move from class m_1 to class m_2 in period t . We start by analyzing these subgroups.

First fix a t and (s, m_1, m_2) with $m_1 < m_2$ and $\chi_{m_1}^t = 1$. We calculate the probability that the $I^t(s, m_1, m_2)$ companies can move from m_1 to m_2 as a function of the parameters to be estimated. Since the tendency variable $\bar{\chi}_{m_1} = 1$, the only possibility for a deterioration $m_1 \rightarrow m_2$ to happen is that $\delta_n^t = 1$ for all the corresponding companies (all other realizations of δ_n^t yield probability 0). The probability is therefore

$$q_{m_1, s}^{I^t(s, m_1, m_2)} p_{m_1, m_2}^{I^t(s, m_1, m_2)}.$$

Now consider the case that $m_1 \geq m_2$ and $\bar{\chi}_{m_1} = 1$. In this case the corresponding companies have the possibility to move from $m_1 \rightarrow m_2$ either by a realization of ξ_n^t (if the $\delta_n^t = 1$) or by a realization of η_n^t (if $\delta_n = 0$). Since all the combinations of these two possibilities have to be considered, the probability is

$$\sum_{n=0}^{I^t} \binom{I^t}{n} \left(\frac{(1 - q_{m_1, s}) p_{m_1, m_2}}{p_{m_1}^+} \right)^n (q_{m_1, s} p_{m_1, m_2})^{I^t - n} = p_{m_1, m_2}^{I^t} \left(\frac{q_{m_1, s} (p_{m_1}^+ - 1) + 1}{p_{m_1}^+} \right)^{I^t}$$

where we abbreviate $I^t(s, m_1, m_2)$ by I^t .

We now split up all the moves in a period t according to industry sector, starting class and rating class in $(t+1)$ and by the above argument get the following formula

$$\mathbb{P}(X^t = x^t | \chi^t = \bar{\chi}, X^{t-1} = x^{t-1}) = \prod_{s=1}^S \prod_{m_1=1}^M \prod_{m_2=1}^{M+1} f(x^{t-1}, s, m_1, m_2, ; Q, P_\chi)$$

with

$$f(x^{t-1}, s, m_1, m_2, ; Q, P_\chi) = \begin{cases} p_{m_1, m_2}^{I^t} \left(\frac{q_{m_1, s} (p_{m_1}^+ - 1) + 1}{p_{m_1}^+} \right)^{I^t}, & m_1 \geq m_2, \bar{\chi}_{m_1} = 1 \\ p_{m_1, m_2}^{I^t} \left(\frac{q_{m_1, s} (p_{m_1}^- - 1) + 1}{p_{m_1}^-} \right)^{I^t}, & m_1 < m_2, \bar{\chi}_{m_1} = 0 \\ q_{m_1, s} p_{m_1, m_2}^{I^t}, & \text{otherwise.} \end{cases}$$

The likelihood function (3) can now be written as

$$\begin{aligned} L(X; Q, P_\chi) &= \prod_{t=2}^T \sum_{\bar{\chi} \in \{0,1\}^M} P_\chi(\chi^t = \bar{\chi}) \mathbb{P}(X^t = x^t | \chi^t = \bar{\chi}, X^{t-1} = x^{t-1}) \\ &= \prod_{t=2}^T \sum_{\bar{\chi} \in \{0,1\}^M} P_\chi(\chi^t = \bar{\chi}) \prod_{s, m_1, m_2} f(x^{t-1}, s, m_1, m_2, ; Q, P_\chi). \end{aligned}$$

The above function is clearly non-convex and since it consists of mix of sums and products this problem also cannot be solved by a logarithmic transform.

Maximizing the above likelihood for given data X in the parameters P_χ and Q amounts to solving the following constrained optimization problem

$$\begin{aligned} \max_{Q, P_\chi} \quad & L'(X; Q, P_\chi) \\ \text{s.t.} \quad & q_{m, s} \in [0, 1] \\ & \sum_{\bar{\chi}: \bar{\chi}_i = 1} P_\chi(\bar{\chi}) = p_{m_i}^+, \quad \forall i : 1 \leq i \leq M \\ & \sum_{\bar{\chi}: \bar{\chi}_1 = 0} P_\chi(\bar{\chi}) = 1 - p_i^+. \end{aligned} \tag{4}$$

where

$$L'(X; Q, P_\chi) = \sum_{t=2}^T \log \left(\sum_{\bar{\chi} \in \{0,1\}^M} P_\chi(\chi^t = \bar{\chi}) \prod_{s, m_1, m_2} f'(x^{t-1}, s, m_1, m_2, ; Q, P_\chi) \right)$$

and

$$f'(x^{t-1}, s, m_1, m_2, ; Q, P_\chi) = \begin{cases} \left(\frac{q_{m_1, s} (p_{m_1}^+ - 1) + 1}{p_{m_1}^+} \right)^{I^t}, & m_1 \geq m_2, \bar{\chi}_{m_1} = 1 \\ \left(\frac{q_{m_1, s} (p_{m_1}^- - 1) + 1}{p_{m_1}^-} \right)^{I^t}, & m_1 < m_2, \bar{\chi}_{m_1} = 0 \\ q_{m_1, s}^{I^t}, & \text{otherwise.} \end{cases}$$

The modified log-likelihood L' is numerically more tractable than the original likelihood function, because of the logarithm and the omission of the terms $p_{m_1, m_2}^{I^t}$. Furthermore it is obvious that both extremes are at the same value and therefore yield the same maximum likelihood estimator.

Since the problem is non-convex and the amount of parameters is too large to employ standard global optimization techniques, we use heuristic global optimization techniques to solve (4). A detailed description of the algorithms used and their properties can be found in [10].

For the rest of the paper we will assume that the parameters (Q, P_χ) are estimated via a maximum likelihood approach. The estimation is based on yearly historical rating data for 10166 companies from all over the world produced by Standard & Poor's over a time horizon of 23 years (1985 - 2007). The data set comprises of 87296 observations of rating transitions (not all the companies are rated over the whole time horizon). We number the 10 Standard & Poor's rating classes from 1 to 10, 1 being AAA and 10 the default class. To reduce the number of parameters the 10 rating classes are clubbed in the following way: $1 \leftarrow \text{AAA, AA}$, $2 \leftarrow \text{A}$, $3 \leftarrow \text{BBB}$, $4 \leftarrow \text{BB, B}$, $5 \leftarrow \text{CCC, CC, C}$, $6 \leftarrow \text{D}$ to obtain a reduced set of 6 rating classes ($M = 5$). We estimate the matrix of transition probabilities P by simple counting as

$$P = \begin{pmatrix} 0.9191 & 0.0753 & 0.0044 & 0.0009 & 0.0001 & 0.0001 \\ 0.0335 & 0.8958 & 0.0657 & 0.0036 & 0.0006 & 0.0009 \\ 0.0080 & 0.0674 & 0.8554 & 0.0665 & 0.0011 & 0.0016 \\ 0.0039 & 0.0092 & 0.0794 & 0.8678 & 0.0244 & 0.0153 \\ 0.0023 & 0.0034 & 0.0045 & 0.1759 & 0.6009 & 0.2131 \\ 0 & 0 & 0 & 0 & 0 & 1 \end{pmatrix}.$$

Note that in our data set we have transitions from every (non default) rating class to every other rating class and therefore have no problems with probabilities which are estimated to be equal to 0.

Additionally we incorporate information on industry sectors by considering the following 6 industry classes (according to SIC classification scheme) Mining and Construction (1), Manufacturing (2), Transportation, Technology, and Utility (3), Trade (4), Finance (5), and Services (6).

The choices above leave us with 62 variables to be estimated. The estimated matrix Q is given by:

$$\begin{pmatrix} 0.1981 & 0.0818 & 0.0138 & 0.0001 & 0.1467 & 0.3089 \\ 0.3854 \cdot 10^{-7} & 0.2008 \cdot 10^{-8} & 0.0655 & 0.8457 \cdot 10^{-6} & 0.0609 & 0.0356 \\ 0.2732 \cdot 10^{-10} & 0.3337 \cdot 10^{-6} & 0.0344 & 0.0005 & 0.0494 & 0.1752 \cdot 10^{-5} \\ 0.0299 & 0.0487 & 0.1518 & 0.0341 & 0.0076 & 0.0300 \\ 0.0816 & 0.1739 & 0.4437 & 0.4092 & 0.2482 \cdot 10^{-5} & 0.0000 \end{pmatrix}$$

while the joint probability function for the χ can be found in Table 1.

4 Credit Default Swap Indices

Below we describe how to use the econometric model for credit rating transitions to design portfolios of structured credit products taking the risk resulting from the uncertainty of future payoffs into account. More specifically we want to construct portfolios of Collateralized Debt Obligations (CDO) based on Credit Default Swap Indices (CDX).

In this section we outline the setting for the portfolio optimization carried out in Section 6, discuss the concept of a CDX, and specify the payoff function of a CDO based on a CDX, which in turn is based on the credit events of single companies.

The payoffs of CDX contracts are based on the performance of portfolios of so called Credit Defaults Swaps (CDS) contracts.

The basic idea of a CDS contract is that the buyer of the contract transfers her credit risk associated with the loans to a certain third party (usually called the reference entity) to the seller of the contract, i.e. the seller insures the buyer against the possible losses resulting from a credit event of the reference entity. In case of a credit event the losses of the buyer are covered by the seller of the contract (cash settlement)³. A credit event can be a default

³There are also other forms of settlement for CDS contracts other than the cash settlement. Some contracts

Rating Class					Probability	Rating Class					Probability

Table 1: Probability function of χ , i.e. joint distributions of up and down moves in the different rating classes. The first 5 columns of the above table describe the event, i.e. the combination of up and down moves in the different classes (1 being a non-deteriorating move, while 0 is a deteriorating move), while the last column gives the estimated probability.

of the reference entity or any other event decreasing the credit quality such as failure to pay or restructuring. We will focus on default events as the only credit events in this paper.

In exchange for the insurance provided by the seller of the contract the buyer pays a certain percentage of the insured amount (the notional) every quarter. Note that a CDS contract often takes the form of a mere bet: the two parties engage in the contract without the existence of underlying loans to the reference identity.

A CDX is a portfolio of simple CDS contracts. In all cases observed in practice the weighting of the individual contracts is uniform, i.e. every CDS contract contributes equally to the overall notional of the CDX contract. As of now there are two companies providing CDX contracts (differing in composition, maturity as well as date of issue): iTraxx for European companies and DJ CDX for the U.S. market.

In this paper we analyze so called CDX tranches, which are synthetic collateralized debt obligations based on CDX. Each buyer of a CDX tranche buys a particular segment of the CDX loss distribution. Typical tranches are equity (0-3%), mezzanine (3-6%), senior (6-9% and 9-12%) and super senior (12-21%). If the tranching is designed like above the first three percent of losses are absorbed by the equity tranche, the next three percent by the mezzanine tranche and so on, i.e. if for example 2% of the notational value of the CDX defaults, then only the buyers of the equity tranche face losses. The buyers of the different tranches receive different spreads on their invested capital.

We assume that we have an asset universe of $\mathcal{N} = \{1, \dots, N\} \subseteq \mathbb{N}$ companies which can be used as reference entities of CDS contracts included in the CDX. The payment streams generated by the contract will be viewed from the risk buyers side, i.e. positive numbers indicate profits for the risk buyer of the CDX tranche.

specify that in case of a credit event of the reference identity the buyer of the CDS hands the seller a bond with face value equal to the notional amount of the CDS contract in exchange for a cash payment of the notional (physical settlement). For simplicity we will stick to cash settlement in this paper.

To describe a specific tranche C of a CDX contract we have to know the following parameters:

1. The assets $\mathcal{A}_C \subseteq \mathcal{N}$ that make up the CDX and the notional value $N(C, t, n)$ with which the CDS corresponding to asset $n \in \mathcal{A}_C$ enters the CDX. Note that the notional value of a company n can drop to zero due to a credit event during the period for which the CDX is issued, hence the time dependence of the notional. We denote the notional value of the whole CDX at time t by $N(C, t)$.
2. The tranching specified by the so called attachment point $\alpha_C \in [0, 1)$ and the detachment point $\beta_C \in (0, 1]$, i.e. the point where the contract begins absorbing losses and the point where everything in the tranche is lost.
3. The maturity T_C of the contract.
4. The spread S_C of the contract, i.e. the positive difference of paid interest rates to the risk free interest.
5. The recovery rate R_C , i.e. the fraction of the notional assigned to a CDS which can be recovered in the case of the default of the corresponding reference entity. For the sake of simplicity we assume this quantity to be non-stochastic and the same for all companies n and note that an extension to non-uniform recovery rates would require only trivial modifications of the methods presented in this paper. Even the most realistic case – namely stochastic recovery rates – could easily be incorporated into the proposed Monte-Carlo framework (see for example [19] for a non-parametric model for default rates).

Hence we can specify our contract as $C = (\mathcal{A}_C, \alpha_C, \beta_C, S_C, T_C, R_C)$.

To simplify the problem, we assume that the contributions of every individual debtor to the CDX are the same, i.e.

$$N(C, 0, n) = \frac{N(C, 0)}{|\mathcal{A}_C|}.$$

As mentioned earlier, in practice this is not a restriction, since all CDX products currently available on the market have this simple structure. It will become obvious that the equal weights are not crucial in our approach and all the evaluation formulas can be extended in a straightforward manner to the case where the assets have different weights. Having made this assumption the percentage of overall losses of the CDX contract that C belongs to can be written as

$$L_C^t = \frac{D_C^t}{|\mathcal{A}_C|}$$

where D_C^t is the number of defaults of reference entities of CDS contracts in the CDX until period t . We now can write $N(C, t)$ as

$$N(C, t) = \begin{cases} \frac{N(C, 0) \left(\beta_C - \frac{D_C^t}{|\mathcal{A}_C|} \right)}{\beta_C - \alpha_C}, & \alpha_C \leq L_C^t \leq \beta_C \\ N(C, 0), & L_C^t < \alpha_C \\ 0, & L_C^t > \beta_C. \end{cases}$$

As mentioned above it is furthermore assumed, that the recovery rate R_C is non-stochastic and the same for all the debtors in the CDX contract. This assumption simplifies the valuation, since the order of the default events does not influence the amount to be paid by a particular risk buyer.

If we divide the time period from the starting of the contract until T_C into T equal time periods (usually years), the random discounted returns arising from the CDX tranche C can

be written as

$$\begin{aligned}\mathcal{R}(C) &= -N(C, 0) + \sum_{t=1}^T r_t \left[N(C, t)(S_C + i_t) + R(N(C, 0) - N(C, t))i_t \right] \\ &+ r_T \left[N(C, T) + R(N(C, T) - N(C, 0)) \right]\end{aligned}$$

where i_t is 1 plus the risk-free rate of return in period t and r_t is the discount rate for period t . $\mathcal{R}(C)$ is random since it depends on the number of default events D_C^t of the companies the individual CDS in the CDX are based on. Note that if a company defaults the recovery amount is kept by the issuer of the CDX and paid out at the maturity of the contract – in the meantime the capital yields the risk free interest for the risk buyer.

The above payout structure corresponds to the so called *funded* version of CDX products, meaning that the notional amount has to be actually paid in the beginning and the capital yields an interest rate of $(S_C + i_t)$ in period t . Alternatively one could consider *unfunded* CDX products where no payment is made at the beginning of the contract, but only when defaults actually occur. If there is no spread in the market for risk free capital the two contracts yield the same payouts. Since we use a simulation based pricing approach the methods presented here are not specific to a particular form of contract.

Other than the losses from defaults of companies, the CDX tranche can also change value because of changes of creditworthiness of debtors that do not involve a default event. Such changes in price are not important if the contract is held until maturity⁴. If however the contract is sold before maturity these changes also have to be considered. In this paper we will assume that the buyer of the CDX tranche holds the contract until maturity.

5 Calculation of Spreads

Usually CDS and thereby CDX tranches are priced by comparing expected values of the payoffs and the obligations from the contract. Using "risk free" evaluation techniques the expected values (under the risk free martingale measure) of these two quantities are usually equated to price the contract. Obviously the approach taken here does not permit analytical solutions in dependence of model parameters. In this section – as a first test of the presented model – we compute rates for different CDX tranches by equating payoffs and obligations as described above.

We try to calculate "fair spreads" for CDO's on CDX tranches using the real world (or physical) probability measure obtained by samples of the model discussed in the previous section and compare the obtained spreads with the spreads offered at the market. This serves as a first empirical test of the model. More specifically, we use the model from section 2 and the parameters found in section 3 to generate scenarios for the rating transitions of all the reference entities of CDS products which are included in the CDX of interest. As a sampling procedure we use simple Monte Carlo, i.e. we simulate the randomness in the model to obtain equally weighted scenarios. Given these scenarios we can calculate scenarios for the return of a CDX tranche C by evaluating $\mathcal{R}(C, \xi^i)$ for the specific scenarios ξ^i of joint rating transitions of the companies in $\mathcal{A}_C$.

To check our model for consistency with market data, we calculate spreads for different tranches $C = (\mathcal{A}_C, \alpha_C, \beta_C, S_C, T_C, R_C)$ of a given CDX product and compare these spreads with spreads offered in the market. More specifically we compute S_C^* such that

$$\mathbb{E}(\mathcal{R}(C^*)) = 0 \tag{5}$$

⁴This statement is not quite correct if we also consider the effects of changed book values due to rating changes of the reference entities making up the CDX contracts. This may result in changed tax burden due to mark to market valuation of the portfolio. For the sake of simplicity we will not consider such effects, since these also depend on the overall situation of the company managing the portfolio.

Table 3: Spreads that fulfill (5) for the different tranches and maturities of iTraxx Europe Series 9. Differences to observed market spreads from Table 2 are given in brackets.

for a CDX tranche $C^* = (\mathcal{A}_C, \alpha_C, \beta_C, S_C^*, T_C, R_C)$. Given a set of return scenarios and the other parameters of the contract C the spread S_C^* can easily be found by simple line search methods.

For our experiment we consider the *iTraxx Europe Series 9 Version 1* for the maturities 5 years, 7 years and 10 years. The *iTraxx Europe* consists of 125 companies with ratings varying from AAA to BBB (i.e. investment grade) at the initiation of an index series. All companies enter the iTraxx with the same weight. The spreads observed on the market are given in Table 2.

For the sake of simplicity we adopt the iTraxx standard estimate for the recovery rate for all the companies and set $R = 0.4$. We furthermore assume a discount rate of 5%. Using this information we simulate 10000 credit rating scenarios over a horizon of 10 years for the 125 involved companies. Table 3 gives the fair spreads which fulfill (5) for the different tranches and maturities.

The spreads for the respective equity tranches are computed under the assumption of prepayments given in Table 2 – this also explains the possibility of negative interest rates for these tranches. It can be observed that the calculated spreads are lower than the observed market spreads. This is intuitively quite clear, since we use the physical probability measure obtained by sampling from the coupled Markov chain model and calculate mere expectations under this model. Thereby the risk inherent in the products is not taken into account at all, and the fair spreads are lower than the actual market spreads. This is also reflected in the

Figure 1: Loss distributions of the mezzanine (a), the two senior (b) & (c) and the super senior (d) tranche of iTraxx Europe, Series 9 with 10 years maturity. The average loss is depicted by a solid line the $VaR_{0.9}$ by a dashed line and the $VaR_{0.99}$ by a dotted line. For (a) and (b) a kernel density estimator was used to depict the distributions. All the computations are performed with data till the 31.03.2008.

differences to the market rates, which are consistently the highest for the equity tranches (i.e. the most risky ones) and gradually decrease with the seniority of the tranche - i.e. the observed differences to the market are due to varying riskiness of the products and can therefore be viewed as risk premiums paid by the market.

As a byproduct of the above analysis we obtain the loss distributions of all the CDX tranches under investigation. The loss distribution of the 10 Year mezzanine, the 10 year senior tranches as well as the 10 year super senior tranches of the iTraxx are plotted in figure 1. The tranches are chosen to demonstrate the diminishing riskiness of the tranches with higher seniority: while the mezzanine and the first senior tranche still exhibit a long right tail indicating a high risk of big losses the distributions of the second senior and the super senior tranches are fairly concentrated around the mean with only very few loss scenarios. As mentioned above, this fact serves as an intuitive justification of the differences of the risk free spreads calculated in this section to the actual market rates.

In the next section we will adopt a more explicit notion of risk and create decision models which can be used to design portfolios of CDX tranches with more favorable risk characteristics as the single contracts investigated in this section.

6 Portfolio Optimization

In this section we want to make use of the distributional information provided in the model (especially the dependency structures between different companies and thereby different CDX products). For the assessment of additional expected profits incurred by a financial

product relative to an existing portfolio the joint distribution of the returns is obviously irrelevant, since the expectation is a linear operator. However, the risk associated with a particular portfolio of assets is dependent on the exposure of the whole portfolio. This exposure in turn hinges on the dependencies between the positions in the portfolio.

In practice CDX tranches and similar contracts are often analyzed in isolation without explicitly considering the portfolio of contracts which the newly acquired contract is part of. Our aim in this section is to design a portfolio wide risk assessment and optimization framework by using the available information on the joint default probabilities and thereby on joint returns of different CDX tranches. This information is contained in the scenarios used in the previous section to calculate fair spreads.

We will demonstrate numerical examples which show that the portfolio view is clearly advantageous in the sense that it allows for substantial reduction of risk of the positions (holding returns fixed).

For our numerical example we use the Conditional Value-at-Risk at level α ($CVaR_\alpha$) as a risk measure. Given a random variable X , the Conditional Value-at-Risk at level α of X is defined as (see [2] and [20])

$$\begin{aligned} CVaR_\alpha(X) &= \frac{1}{1-\alpha} \int_\alpha^1 F_X^{-1}(x) dx \\ &= \max \left\{ a - \frac{1}{\alpha} \mathbb{E}([X - a]^-) : a \in \mathbb{R} \right\}, \end{aligned}$$

where F_X is the distribution of X and $F_X^{-1}(x) = \inf \{t : F_X(t) \geq x\}$ is its generalized inverse. In principle there is a wide range of available risk measures which can be effectively used in optimization frameworks. Our choice is motivated by:

1. The favorable theoretical properties of $CVaR$. Since $CVaR$ is a convex risk measure it leads to sensible decisions from an economic point of view, favoring diversification over concentration - a property that for example the Value-at-Risk lacks (see [18]).
2. The fact that $CVaR$ is piecewise linear (in the finite scenario setting) making problem (6) tractable numerically (see formulation (7) below).
3. The fact that $CVaR$ is closely related to VaR which plays an important role in the Basel accord - the current regulatory framework for banks. In fact it is easy to see that $CVaR$ is always bigger than VaR , making portfolios which have favorable $CVaR$ -characteristics also attractive from a VaR perspective.

We assume that there exists a range of different CDX contracts $\mathcal{C} = (C_1, \dots, C_d)$. The aim is to solve the following mean risk problem using the CDX tranches as investment possibilities.

$$\begin{aligned} \min_w \quad & CVaR_\alpha(w^\top \mathcal{R}(\mathcal{C})) \\ \text{s.t.} \quad & \mathbb{E}(w^\top \mathcal{R}(\mathcal{C})) \geq \mu \\ & \sum w_i = 1 \\ & w_i \in [a, b], \quad \forall i : 1 \leq i \leq d \end{aligned} \tag{6}$$

where by slight abuse of notation $w^\top \mathcal{R}(\mathcal{C}) = \sum_{i=1}^d w_i \mathcal{R}(C_i)$ and the decision variables are the portfolio weights $w = (w_1, \dots, w_d) \in \mathbb{R}^d$ constrained by the bounds $a, b \in \mathbb{R}$.

We know that in a scenario framework the above problem can be computed by solving the following linear optimization problem (see [20])

$$\begin{aligned} \min_w \quad & a + \frac{1}{|\mathcal{S}|} \sum_{s \in \mathcal{S}} z^s \\ \text{s.t.} \quad & \frac{1}{|\mathcal{S}|} \sum_{s \in \mathcal{S}} w^\top \xi^s \geq \mu \\ & \sum w_i = 1 \\ & w_i \in [a, b], \quad \forall i : 1 \leq i \leq d \\ & w^\top \xi^s - a \leq z^s, \quad \forall s \in \mathcal{S} \\ & z^s \geq 0, \end{aligned} \tag{7}$$

Figure 2: Return distribution of the mezzanine tranche of iTraxx Europe, Series 9 with 10 years maturity. All the computations are performed with data until the 31.03.2008.

	$VaR_{0.9}$	$CVaR_{0.9}$	$VaR_{0.99}$	$CVaR_{0.99}$
10Y / Mezzanine	0.1599	0.0333	0.4240	0.3197
Run 1	-0.1825	-0.3009	0.2835	0.0375
Run 2	-0.0925	-0.1299	-0.0059	-0.0522

Table 4: The table shows the Value-at-Risk as well as the Conditional Value-at-Risk at level $\alpha = 0.9$ and $\alpha = 0.99$ for the loss distribution of the original CDO tranche as well as for the portfolio resulting from optimization run 1 (minimize $CVaR_{0.9}$) and from optimization run 2 (minimize $CVaR_{0.99}$).

where $\mathcal{S}$ is the finite set of equally probable scenarios, while z^s are auxiliary variables required for the modeling of $CVaR$ as linear program and ξ^s is the vector of losses from the contracts C_i in scenario s , i.e. $\xi^s = -(\mathcal{R}(C_1, s), \dots, \mathcal{R}(C_d, s))$.

Our setup for the numerical tests is the following: we choose one iTraxx tranche (specifically the 10 year mezzanine tranche) and investigate its return distribution with the support of 10.000 simulated scenarios from our model with the estimated parameters. Figure 2 shows the distribution of the returns of this tranche. The distribution exhibits the typical long left tail that is commonly observed from portfolios of loans and synthetic products based on loan portfolios. While the mean discounted return of the tranche is 0.3133, the $VaR_{0.9}$ and the $VaR_{0.99}$ are considerably larger indicating the high risk associated with the product.

The idea is to try to find a portfolio of all CDO tranches based on the iTraxx Europe, Series 9, which has the same expected return as the 10 year mezzanine tranche, but more favorable risk characteristics (in terms of $CVaR$). We therefore solve problem (7) with the parameters $\mu = 0.3133$, $a_i = b_i = 0.5$ for all $1 \leq i \leq d$ and $\alpha = 0.1$ and obtain the portfolio shown in Figure 3.

The optimal portfolio is clearly less risky (yielding the same expected return): while the distribution still is heavy tailed (on the left), it contains much less probability mass which is also reflected by the drastic improvements of $CVaR_{0.9}$ as well as $VaR_{0.9}$ relative to the original return distribution (see Table 4 for an overview).

The optimization run was repeated for the parameter $\alpha = 0.99$. The portfolio and loss

Figure 3: Part (a) of the figure shows the optimal portfolio found by solving problem (6) with parameters $\mu = 0.3133$ and $\alpha = 0.9$. The y-axis labels give the product (1/5Y is the equity tranche with 5 year maturity) while the x-axis depicts the portfolio weights. A bar to the left means that the portfolio is short in the respective position while a bar to the right indicates a long position.

distribution for this run are depicted in Figure 4. The lower value of α is reflected in a structurally different shape of the return distribution. The portfolio yields a surprisingly low $VaR_{0.9}$ and $VaR_{0.99}$ while still yielding the same expected discounted returns as the original CDX tranche.

Since the risk characteristics of both portfolios are clearly preferable to the original one, it is shown that a portfolio view which explicitly incorporates dependencies between the products and the risk originating from the joint distributions of the losses yields better decisions and avoids positions that have high concentration risk.

7 Conclusion

In this paper we presented methods to estimate the parameters of the rating transition model proposed in [11] using a maximum likelihood approach. Subsequently the estimates are used to generate a set of scenarios for the joint rating transitions of the companies included in the iTraxx, Series 9 index.

The calibrated model was used to show that even financial products, which are *buffered against losses* by tranching, can have quite unfavorable return distributions. This result hinges on the explicit modeling of the joint distribution of defaults, which is such that it is capable of capturing effects which resemble a crisis situation: i.e. systematic simultaneous defaults of many debtors.

The developments on financial markets in the two years after the emergence of the sub-prime crisis in 2007 demonstrated that structured products like CDX tranches should not be viewed as stand alone instruments, which are constructed in a way that further risk control is superfluous but merely as single assets whose analysis has to be integrated in a company wide risk management. We used a bottom up approach to assess the riskiness of such structured products and thereby enabling a correct assessment of the risk inherent in these contracts. The presented framework can be used to derive strategies to mitigate the risk emanating from CDX tranches by solving a portfolio selection problem where the asset universe consists of various CDX contracts. It turned out that even in this simple framework with few hedging instruments a carefully selected portfolio of contracts clearly outperforms a single contract.

The presented optimization methods offer a convenient framework which has two advantages: firstly it allows the use of arbitrary scenarios for company default as an input, which

Figure 4: Part (a) of the figure shows the optimal portfolio found by solving problem (6) with parameters $\mu = 0.3133$ and $\alpha = 0.99$. The y-axis labels give the product (1/5Y is the equity tranche with 5 year maturity) while the x-axis depicts the portfolio weights. A bar to the left means that the portfolio is short in the respective position while a bar to the right indicates a long position. Figure (b) shows the loss distribution of the optimal portfolio as well as the mean (solid line) the $VaR_{0.9}$ (dashed line) and the $VaR_{0.99}$ (dotted line).

makes it possible to use sophisticated statistical models to predict the joint rating (and default) behavior of companies and secondly it is flexible enough to reproduce the complex contract structures of CDX products without any problems. The flexibility of the model makes it possible to relax most of the assumptions made in this paper to make the model even more realistic. In particular it would be easily possible to incorporate stochastic models for the interest rates and the loss given default as well as transaction costs and varying contract details.

The mentioned flexibility of the approach together with the numerical feasibility of large problem instances make the outlined methods interesting for companies and investors who are faced with the problem of risk management in the context of corporate bonds and structures credit products.
